

A novel GPU-based sonar simulator for real-time applications

Abstract

Sonar simulation requires great computational effort due to the complexity of acoustic physics mainly when applied in the underwater environment. This fact turns the challenge of reproducing sensor data into a non-trivial task. On the other hand, simulation of sonar operation data allows to evaluate algorithms and control systems without going to the real underwater environment; that reduces the costs and risks of in-field experiments. This paper proposes a novel real-time underwater imaging sonar simulator, which uses the OpenGL shading language (GLSL) chain, and is able to simulate two main types of sonar sensors: mechanical scanning imaging sonars (MSIS) and forward-looking sonars (FLS). The virtual underwater simulation was conceived based on three frameworks: (i) OpenSceneGraph (OSG) reproduces the ocean visual effects, (ii) Gazebo deals with physics effects, and (iii) the Robot Construction Kit (Rock) controls the sonar in underwater environments. The proposed sonar simulation exploits the rasterization pipeline in order to build a matrix comprised of echo intensity, distance and angular distortion, being all calculated over object shapes in the 3D rendered scene. Sonar-intrinsic speckle noise and object material properties are also considered as part of the sonar image. Our evaluation demonstrated that the proposed method is able to operate with high frame rate, as well as realistic sonar image quality in different virtual underwater scenarios.

Key words: Simulated sensor data, sonar imaging, GPU-based processing, Robot Construction Kit (Rock), Underwater robotics.

1. Introduction

1 Simulation is an useful tool for designing and programming
2 autonomous robot systems. That allows evaluating robot behav-
3 ior, without dealing with physical hardware or decision-making
4 algorithms and control systems in real-time trials, as well as
5 costly and time-consuming field experiments.

6 When working with autonomous underwater vehicles (AUVs),
7 simulation of facilities are specially relevant. AUVs usually de-
8 mand expensive hardware and perform long-term data gather-
9 ing operations, taking place in restrictive sites. As AUV does
10 not need umbilical cable, and the underwater communication
11 carries on by unreliable acoustic links, the robot should be able
12 to make completely autonomous decisions, even with low-to-
13 zero external assistance. While the analysis and interpretation
14 of sensor data can be performed in a post-processing step, a
15 real-time simulation is strongly needed for testing and evalua-
16 tion of vehicle's motion responses, avoiding involved risks on
17 real world rides.

18 AUVs usually act below the photic zone, with high turbid-
19 ity and huge light scattering. This makes the quality of image
20 acquisition by optical devices limited by a short range, and also
21 artificially illuminated and clear visibility conditions. To tackle
22 with that limitations, high-frequency sonars have been used pri-
23 marily on AUVs' navigation and perception systems. Acoustic
24 waves emitted by sonars are significantly less affected by water
25 attenuation, aiding operation at greater ranges even as low-to-
26 zero visibility conditions, with a fast refresh rate. Although
27 sonar devices usually solve the main shortcomings of optical
28 sensors, they provide noisy data of lower resolution and more
29 difficult interpretation.

30 By considering sonar benefits and singularities along with

32 the need to evaluate AUVs, recent works proposed ray tracing-
33 and tube tracing-based techniques to simulate acoustic data with
34 very accurate results, although having a high computational
35 cost [1, 2, 3, 4, 5, 6, 7]. Bell [1] proposed a simulator based
36 on optical ray tracing for underwater side-scan sonar imagery;
37 images were generated by acoustic signals represented by rays,
38 which are repeatedly processed, forming a 2D-array. Coiras and
39 Groen [2] used frequency-domain signal processing to produce
40 synthetic aperture sonar frames; in that method, the acoustic
41 image was created by computing the Fourier transform of the
42 acoustic pulse used to insonify the scene. For forward-looking
43 sonar simulations, Guériot and Sintes [3] introduce a volume-
44 based approach of energy interacting with the scene, and col-
45 lected by the receiving sonar; the sound propagation is defined
46 by series of acoustic tubes, being always orthogonal to the cur-
47 rent sonar view, where the reverberation and objects' surface ir-
48 regularities are also addressed. Saç *et al.* [4] described a sonar
49 model by computing the ray tracing in frequency domain; when
50 a ray hits an object in 3D space, three parameters are calcu-
51 lated to process the acoustic data: the Euclidean distance from
52 the sonar axis, the intensity of returned signal by Lambert Illu-
53 mination model and the surface normal; the reverberation and
54 shadow phenomena are also considered in the scene rendering.
55 DeMarco *et al.* [5] used Gazebo and Robot Operating System
56 (ROS) [8] integration to simulate the acoustic sound pulses by
57 a ray tracing technique, and to produce a 3D point cloud of the
58 covered area; since the material reflectivity was statically de-
59 fined, the final sonar image presented the same intensity values
60 for all points on a single object. Gu *et al.* [6] modeled a forward-
61 looking device where the ultrasound beams were formed by a
62 set of rays; the acoustic image is significantly limited by its rep-
63 resentation using only two colors: white, when the ray strikes

64 an object, and black for shadow areas. Kwak *et al.* [7] evolved
 65 the previous approach by adding a sound pressure attenuation
 66 to produce the gray-scale sonar frame, while the other physical
 67 characteristics related to sound transmission are disregarded.

68 1.1. Contributions

69 This paper introduces a novel imaging sonar simulator, that
 70 can overcome the main limitations of the existing approaches.
 71 As opposed to [1, 2, 3, 4, 5, 6, 7], where the proposed models
 72 simulate a specific sonar type, our model is able to reproduce
 73 two kind of sonar devices: mechanical scanning imaging sonar
 74 (MSIS) and forward-looking sonar (FLS). Also, the underwa-
 75 ter scene is processed during the pipeline rendering on graph-
 76 ics processing unit (GPU), accelerating the simulation process,
 77 guaranteeing real-time simulation, in contrast to the methods
 78 found in [1, 2, 4, 5]. The intensity measured back from the in-
 79 sonified objects depends on the accumulated energy based on
 80 surface normal directions, producing more realistic simulated
 81 scenes, instead of statically defined by the user, as in [5], or in
 82 a binary representation as found in [6, 7]. The speckle noise
 83 is modeled as a non-uniform Gaussian distribution and added
 84 to the final sonar image, performing a more realistic sensing,
 85 differently to [3, 4, 6, 7].

86 The main goal here is to build quality and low time-con-
 87 suming acoustic frames, according to underwater sonar image
 88 formation and operation modes (see Section 2). The shader ma-
 89 trix with depth and normal buffers, and angular distortion values
 90 are extracted from underwater scene, and subsequently fused to
 91 generate the simulated sonar data, as described in Section 3.
 92 Qualitative and time evaluation results for two different sonar
 93 devices are presented in Section 4, and allow for the use of the
 94 proposed simulator in real-time applications.

95 2. Imaging Sonar operation

96 Sonars are echo-ranging devices that use acoustic energy to
 97 locate and survey objects in a desired area. The sonar trans-
 98 ducer emits pulses of sound waves (or ping) until they hit with
 99 any object or be completely absorbed. When the acoustic sig-
 100 nal collides with a surface, part of this energy is reflected, while
 101 other is refracted. The sonar data is built by plotting the echo
 102 measured back versus time of acoustic signal. The transducer
 103 reading in a given direction forms a *beam*. A single beam trans-
 104 mitted from a sonar is illustrated in Fig. 1. The horizontal and
 105 vertical beamwidths are represented by the azimuth ψ and el-
 106 evation θ angles, respectively, where each sampling along the
 107 beam is named as *bin*. The sonar covered area is defined by
 108 R_{min} and R_{max} . Since the speed of sound underwater is known,
 109 or can be measured, the time delay between the emitted pulses
 110 and their echoes reveal how far the objects are (distance r), as
 111 well as how fast they are moving. The backscattered acoustic
 112 power in each bin determines the intensity value.

113 With different azimuth directions, the array of transducer
 114 readings forms the final sonar image. Since all incoming sig-
 115 nals converge to the same point, the reflected echoes could have
 116 been originated anywhere along the corresponding elevation arc

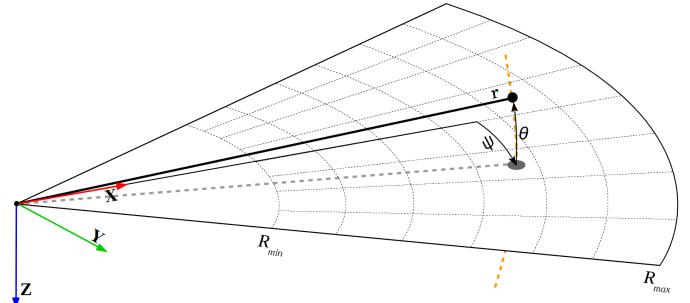

Figure 1: Imaging sonar geometry. By the projection process, all 3D points belonging to the same elevation arc (represented as dashed red line) will be represented to the same image point in the 2D plane. This way, range r and azimuth angle ψ are measured, and elevation angle θ is lost. The sonar covered area is defined by R_{min} and R_{max} .

117 at a fixed range, as depicted in Fig. 1. In the acoustic represen-
 118 tation, the 3D information is lost in the projection into a 2D
 119 image.

120 2.1. Sonar characteristics

121 Although sonar devices overcome the main limitations of
 122 optical sensors, they present more difficult data interpretation
 123 due to:

- 124 (a) **Shadowing:** This effect is caused by objects blocking the
 125 sound waves transmission and causing regions behind, with-
 126 out acoustic feedback. These regions are defined by a
 127 black spot in the image occluding part of the scene;
- 128 (b) **Non-uniform resolution:** The amount of pixels used to
 129 represent an intensity record in the cartesian coordinate
 130 system grows as its range increases. This fact causes im-
 131 age distortions and object flatness;
- 132 (c) **Changes in viewpoint:** Imaging the same scene from dif-
 133 ferent viewpoints can cause occlusions, shadows move-
 134 ments and significant alterations of observable objects [9].
 135 For instance, when an outstanding object is insonified, its
 136 shadow is shorter, as the sonar becomes closer;
- 137 (d) **Low signal-to-noise ratio (SNR):** The sonar suffers from
 138 low SNR mainly due the very-long-range scanning, and
 139 the presence of speckle noise introduced caused by acous-
 140 tic wave interferences [10];
- 141 (e) **Reverberation:** This phenomenon is caused when multi-
 142 ple acoustic waves returning from the same object are de-
 143 tected over the same ping, producing duplicated objects.

144 2.2. Types of underwater sonar devices

145 The most common types of underwater acoustic sonars are
 146 MSIS and FLS. In the former, the sonar image is built for each
 147 pulse, with one beam per reading (see Fig. 2(a)); these sonar
 148 images are usually shown on a display pulse by pulse, and the
 149 head position reader is rotated according to motor step angle.
 150 After a full 360° sector reading (or the desired sector defined
 151 by left and right limit angles), the accumulated sonar data is
 152 overwritten. The acquisition of a scanning image involves a rel-
 153 atively long time, introducing distortions caused by the vehicle

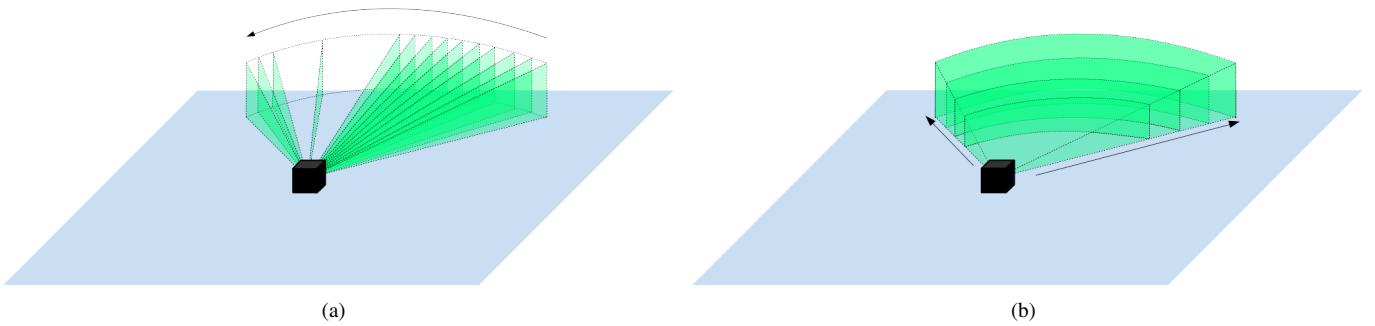

Figure 2: Different underwater sonar readings: (a) From a mechanical scanning imaging sonar and (b) from a forward-looking sonar.

154 movements. This sonar device is generally applied in obstacle
 155 avoidance [11] and navigation [12] applications.

156 As illustrated in Fig. 2(b), the whole forward view of an
 157 FLS is scanned and the current data is overwritten by the next
 158 one in a high frame rate, with n beams being read simultane-
 159 ously. This is similar to a streaming video imagery for real-
 160 time applications. This imaging sonar is commonly used for
 161 navigation [13], mosaicing [9], target tracking [14] and 3D re-
 162 construction [15].

163 3. GPU-based sonar simulation

164 The goal of this work is to simulate two types of underwa-
 165 ter sonar by vertex and fragment processing, with a low com-
 166 putational cost. The complete pipeline of the proposed simu-
 167 lator, from the virtual scene to the simulated acoustic data, is
 168 seen in Fig. 3 and is detailed in the following subsections. The
 169 sonar simulation is written in C++ with OpenCV [16] support
 170 as Rock packages.

171 3.1. Rendering underwater scene

172 The Rock-Gazebo integration [17] provides the underwa-
 173 ter scenario, and allows real-time hardware-in-the-loop simula-
 174 tions. In this framework, Gazebo handles the physical engines,
 175 and the Rock’s visualization tools are responsible by the scene
 176 rendering. The graphical data in Rock are based on OpenScene-
 177 Graph framework, an open source C/C++ 3D graphics toolkit
 178 built on OpenGL. The osgOcean framework is used to simulate
 179 the ocean visual effects, and the ocean buoyancy is defined by
 180 the Gazebo, as described in [17].

181 All scene aspects, such as world model, robot parts (in-
 182 cluding sensors and joints) and other objects presented in the
 183 environment are defined by simulation description files (SDF),
 184 which use the SDFormat [18], a XML format used to describe
 185 simulated models and environments for Gazebo. Visual and
 186 collision geometries of vehicle and sensor robot are also de-
 187 scribed in specific file formats. Each component described in
 188 the SDF file becomes a Rock component, which is based on
 189 the Orocros real-time toolkit (RTT) [19], providing I/O ports,
 190 properties and operations as communication layers. When the
 191 models are loaded, Rock-Gazebo creates I/O ports to allow real-
 192 world or simulated system components interacting with the sim-
 193 ulated models. A resulting scene sample of this integration is
 194 seen in Fig. 4.

195 3.2. Shader rendering

196 GPUs are parallel numeric computing chips specialized to
 197 speed up 2D and 3D graphics processing, reducing the compu-
 198 tational effort of the central processing unit (CPU). The ren-
 199 dering pipeline can be customized by defining programs on
 200 GPU called shaders. A shader is written in OpenGL Shad-
 201 ing Language (GLSL) [20], a high-level language with a C-
 202 based syntax which enables more direct control of graphics
 203 pipeline, which avoids the use of low-level or hardware-specific
 204 languages. Shaders can describe the characteristics of either a
 205 vertex or a fragment (a single pixel). Vertex shaders are respon-
 206 sible by transforming the vertex position into a screen position
 207 by the rasterizer, generating texture coordinates for texturing,
 208 and lighting the vertex to determine each color. The rasteri-
 209 zation results in a set of pixels to be processed by fragment
 210 shaders, which manipulate their locations, depth and alpha val-
 211 ues, and interpolated parameters from the previous stages, such
 212 as colors and textures.

213 In our work, the underwater scene is sampled by a virtual
 214 camera, whose optical axis is aligned with the intended viewing
 215 direction of the imaging sonar device, as well as the covered
 216 range and opening angle. By programming the fragment and
 217 vertex shaders, the sonar data is computed as:

- 218 (a) **Depth** is the camera focal length, calculated by the Eu-
 219 clidean distance to the object surface point;
- 220 (a) **Intensity** presents the echo reflection energy based on
 221 object surface normal angle up to the camera;
- 222 (a) **Angular distortion** is the angle formed from the camera
 223 center column up to the camera boundary column, for
 224 both directions.

225 All those three informations are normalized into the interval
 226 $[0,1]$, where zero means no energy and one means maximum
 227 echo energy for intensity data, respectively. For depth data,
 228 the minimum value portrays a close object while the maximum
 229 value represents a far one, limited by the sonar maximum range.
 230 Angle distortion value is zero in image center column which
 231 increases for both borders to present the half value of horizontal
 232 field of view.

233 In realistic sensing, real-world surfaces usually present ir-
 234 regularities and different reflectance values. To render that in a

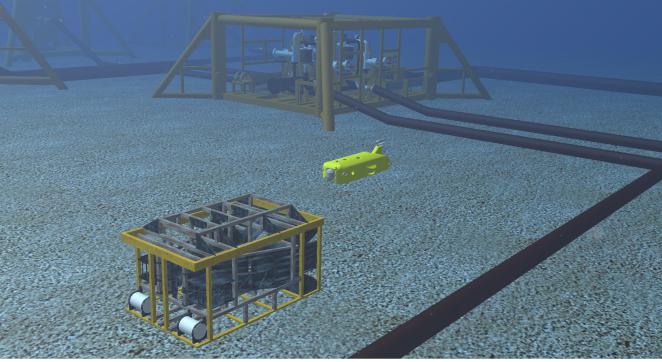

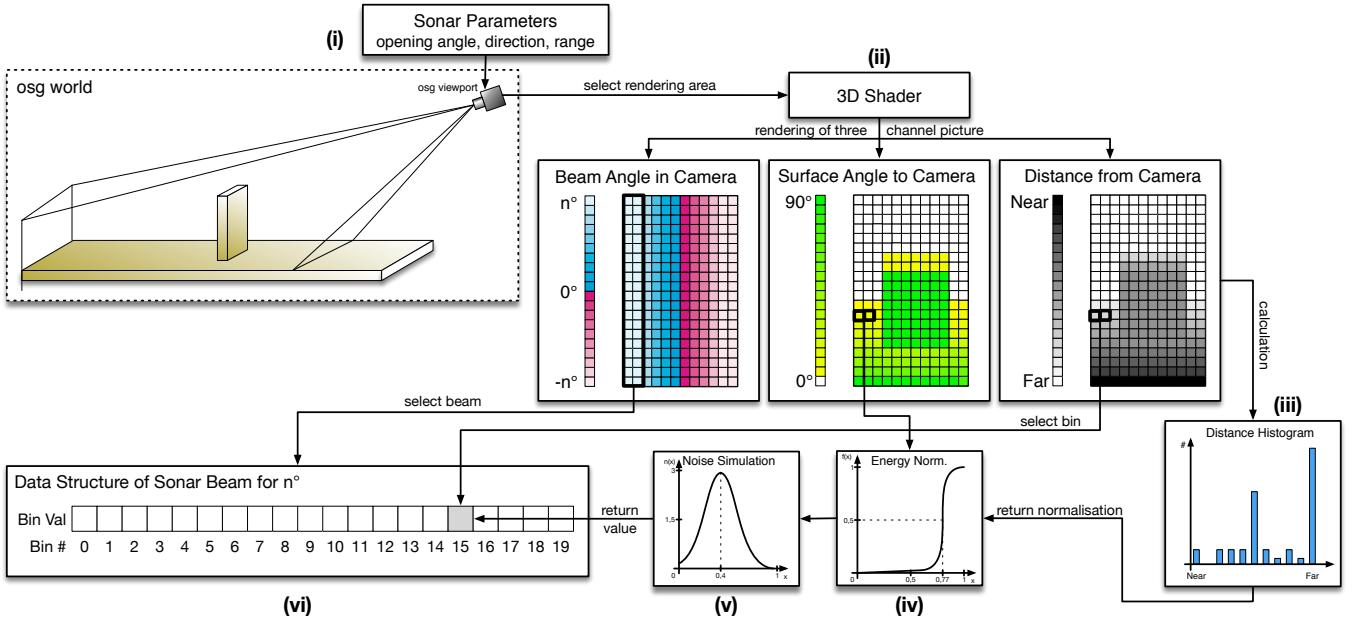

Figure 4: The AUV in Rock-Gazebo underwater scene.

virtual scene, the intensity values can also be defined by a normal maps and material property information. Normal mapping is a perturbation rendering technique to simulate wrinkles and dents on the object surface by passing RGB textures and modifying the normal directions on shaders. This approach consumes less computational resources for the same level of detail, compared to the displacement mapping technique, because the geometry remains unchanged. Since normal maps are built in tangent space, interpolating the normal vertex and the texture, a tangent, bitangent and normal (TBN) matrices are computed to convert the normal values into the world space. Representation of normal mapping process in our approach is seen in Fig. 5.

The reflectance allows to properly describe the intensity received back from observable objects in shader processing, according their material properties. For instance, aluminum has more reflectance than wood and plastic. When an object has its reflectivity defined, the reflectance value ρ is passed to frag-

ment shader and must be positive. As seen in Fig. 6, normal values are directly proportional to the reflectance value ρ . At the end, the shader process provides a matrix with three main data: Intensity, depth and angular distortion.

3.3. Simulating sonar device

The 3D shader matrix is processed in order to build the corresponding acoustic representation. Since the angular distortion is radially spaced over the horizontal field-of-view, where all pixels in the same column have the same angle value, the first step is to split the image in a number of beam parts. Each column is correlated with its respective beam, according to sonar bearings, as seen in Fig. 3. Each beamed sub-image is converted into bin intensities using the depth and intensity data. In a real imaging sonar, the echo measured back is sampled over time and the bin number is proportional to the sensor range. In other words, the initial bins represent the closest distances, while the latest bins are the farthest ones. Therefore a distance histogram is evaluated to group the sub-image pixels with their respective bins, according to the depth value. This information is used to calculate the accumulated intensity of each bin.

Due to the acoustic beam spreading and absorption in the water, the final bins have less echo strength than the first ones, because the energy is lost twice, in the environment. To tackle with that issue, the sonar devices use an energy normalization based on time-varying gain for range dependence compensation, which spreads losses in the bins. In our simulation approach, the accumulated intensity in each bin is normalized as

$$I_{bin} = \sum_{x=1}^N \frac{1}{N} \times S(i_x), \quad (1)$$

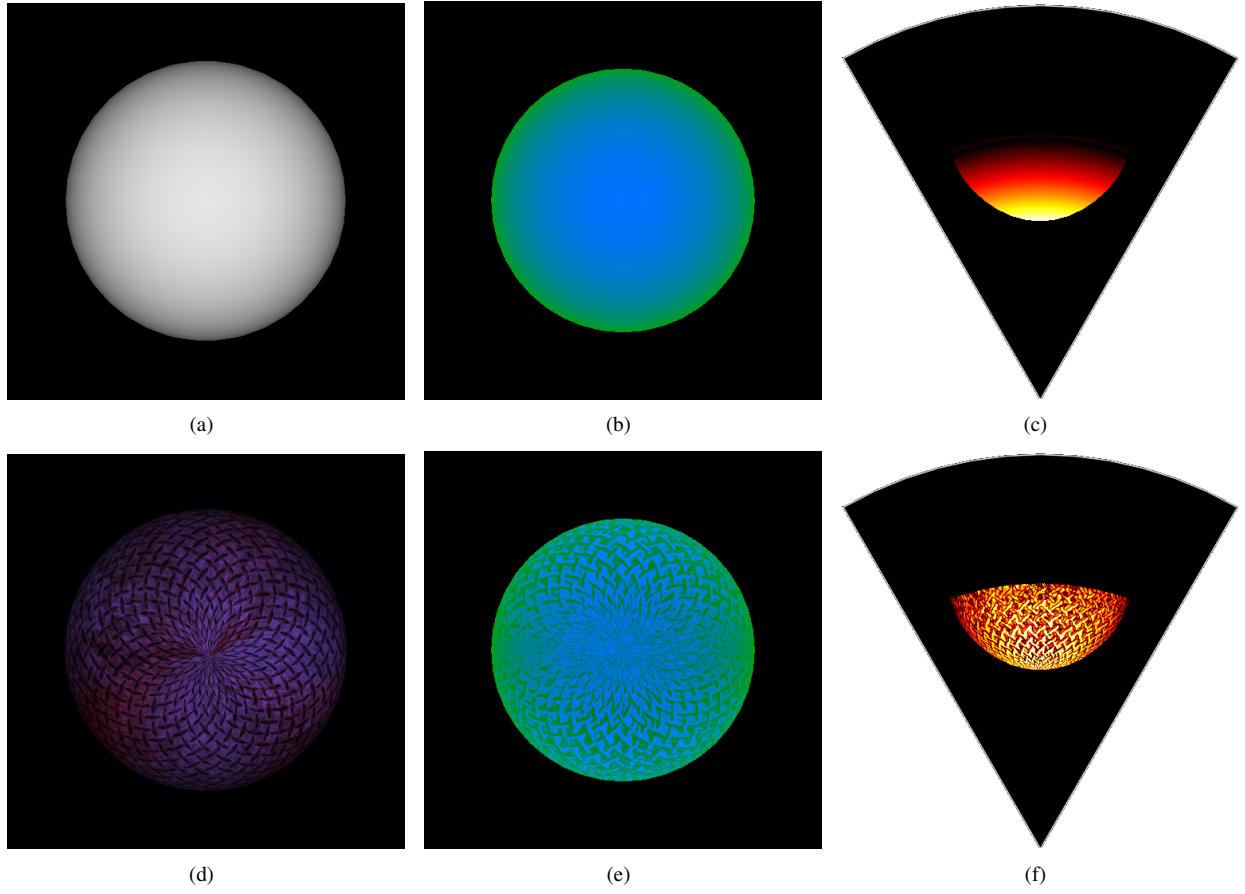

Figure 5: Example of shader rendering with normal mapping processing: A sphere without texture (a) and with texture (d); their respective shader image representation in (b) and (e), where blue is the normal channel and green is the depth one; and the final acoustic image in (c) and (f). By using normal mapping technique, the textures changes the normal directions, and the sonar image details the appearance of object surface, like in real-world sensing.

where I_{bin} is the intensity in the bin after energy normalization, x is the pixel location in the shader matrix, N is the depth histogram value (number of pixels) of that bin, $S(i_x)$ is a sigmoid function, and i_x is the intensity value of the pixel x .

Finally, the sonar image resolution needs to be big enough to fill all informations of the bins. For that, the number of bins involved is in direct proportion to the sonar image resolution.

limit theorem, which states that the sum of many independent and identically distributed random variables tends to behave a Gaussian random variable. A Gaussian distribution is defined by following a non-uniform distribution, skewed towards low values, as seen in Fig. 3, and applied as speckle noise in the simulated sonar image. After that, the simulation sonar data process is performed in each frame.

3.4. Noise model

Imaging sonar systems are disturbed by a multiplicative noise known as speckle, and caused by coherent processing of backscattered signals from multiple distributed targets. These latter ones degrade image quality and the visual evaluation. Speckle noise results in constructive and destructive interferences which are shown as bright and dark dots in the image. The noisy image has been expressed as [21]:

$$y(t) = x(t) \times n(t), \quad (2)$$

where t is the time instant, $y(t)$ is the noised image, $x(t)$ is the free-noise image, $n(t)$ is the speckle noise matrix, and \times symbol defines an element-wise multiplication.

This type of noise is well-modeled as a Gaussian distribution. The physical explanation is provided by the central

3.5. Integrating sonar device with Rock

To export and display the sonar image, the simulated data is encapsulated as Rock's sonar data type, and provided as an output I/O port of a Rock's component.

4. Simulation results and experimental analysis

To evaluate our simulator, experiments were conducted by using a 3D model of an AUV equipped with one MSIS and one FLS, studied in different scenarios. The following devices configuration are summarized in Table 1. As the scene frames are being captured by the sonars, resulting simulated acoustic images are sequentially presented, on-the-fly.

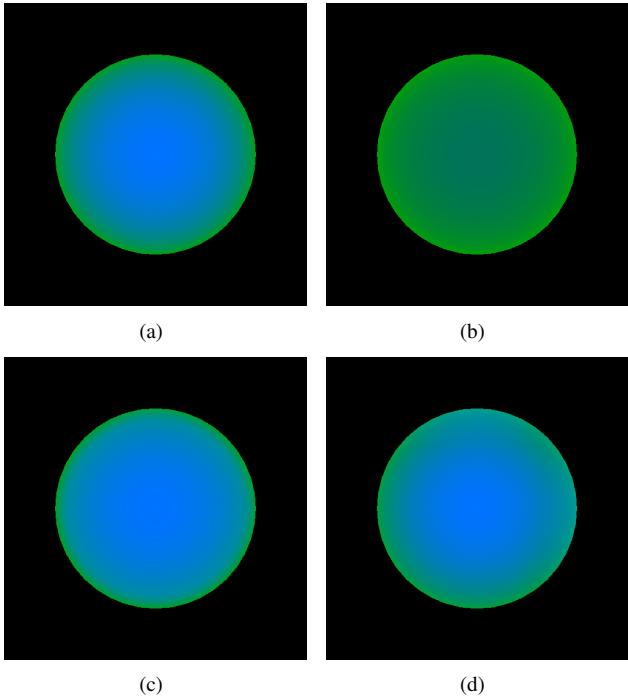

Figure 6: Examples of different reflectance values, ρ , applied in shader image representation, where blue is the normal channel and green is the depth channel: (a) raw image; (b) $\rho = 0.35$; (c) $\rho = 1.40$; and (d) $\rho = 2.12$.

Table 1: Sonar devices configurations used on experimental evaluation.

Device	# of beams	# of bins	Field of view	Down tilt	Motor Step
FLS	256	1000	120° x 20°	20°	-
MSIS	1	500	3° x 35°	0°	1.8°

319 4.1. Experimental evaluation

320 The virtual FLS from AUV was used to insonify the scenes
 321 from three distinct scenarios. A docking station, in parallel
 322 with a pipeline on the seabed, composes **the first scenario** (see
 323 Fig. 7(a)). The target surface is well-defined in the simulated
 324 acoustic frame (see Fig. 7(b)), even as the shadows and speckle
 325 noise. Given the docking station is metal-made, the texture and
 326 reflectivity were set, such as a higher intensity shape was re-
 327 sulted in comparison with the other targets. **The second sce-
 328 nario** presents the vehicle in front of a manifold model in a
 329 non-uniform seabed (see Fig. 7(c)). The target model was in-
 330 sonified to generate the sonar frame from the underwater scene.
 331 The frontal face of the target, as well the portion of the seabed
 332 and the degraded data by noise, are clearly visible in the FLS
 333 image. Also, a long acoustic shadow is formed behind the man-
 334 ifold, occluding part of the scene. **The third scenario** contains
 335 a sub-sea isolation valve (SSIV) structure, connected to a pipe-
 336 line in the bottom (see Fig. 7(e)).

337 Due to sensor configuration and robot position, the initial
 338 bins usually present a blind region in the three simulated scenes,
 339 caused by absence of objects at lower ranges, similar to real im-

340 ages. Also, the brightness of sea-floor decreases, when farthest
 341 from sonar, because of the normal orientation of the surface.

342 The MSIS was also simulated in three different experiments.
 343 The robot in a big textured tank composes **the first scene** (see
 344 Fig. 8(a)). Similar to the first scenario of FLS experiment,
 345 the reflectivity and texture were set to the target. The rotation
 346 of the sonar head position, by a complete 360° scanning, pro-
 347 duced the acoustic frame of tank walls (see Fig. 8(b)). **The**
 348 **second scene** involves the vehicle's movement during the data
 349 acquisition process. The scene contains a grid around the AUV
 350 (see Fig. 8(c)), a MSIS in the front of the AUV is used. This
 351 trial induces a distortion in the final acoustic frame, because the
 352 relative sensor position with respect to the surrounding object
 353 changes while the sonar image is being built (see Fig. 8(d)). In
 354 this case, the robot rotates 20° left during the scanning. **The**
 355 **last scene** presents the AUV over oil and gas structures on the
 356 sea bottom (see Fig. 8(e)). Using a MSIS located in the back of
 357 the AUV, with a vertical orientation, the scene was scanned to
 358 produce the acoustic visualization. As illustrated in Fig. 8(f),
 359 object surfaces present clear definition in the slice scanning of
 360 the sea-floor.

361 The experimental scenarios provided enough variability of
 362 specific phenomena usually found in real sonar images, such as
 363 acoustic shadows, noise interference, surface irregularities and
 364 properties, distortion during the acquisition process and gradi-
 365 ent of acoustic intensities. However, our sonar model also pre-
 366 sented some limitations. For instance, the speckle noise appli-
 367 cation is restricted to regions with acoustic intensity, as shown
 368 in Figs. 7(f) and 8(b). This fact is due to our sonar model,
 369 defined in Eq. 2, be multiplicative. In real sonar images, the
 370 noise also granulates the shadows and blind regions. The sonar
 371 simulator can be improved by inserting an additive noise to our
 372 model. A second feature missing in simulated acoustic images
 373 are the ghost effects caused by reverberation. This lacking part
 374 can be addressed by implementation of a multi-path propaga-
 375 tion model.

376 4.2. Computational time

377 Performance evaluation of the simulator was determined by
 378 considering the suitability to run real-time applications. The
 379 experiments were performed on a laptop with Ubuntu 16.04
 380 64 bits, Intel Core i7 3540M processor running at 3 GHz with
 381 16GB DDR3 RAM memory and NVIDIA NVS 5200M video
 382 card.

383 The elapsed time of each sonar data is stored to compute the
 384 average time, standard deviation and frame rate metrics, after
 385 500 iterations, as summarized in Tables 2 and 3. After chang-
 386 ing the device parameters, such as number of bins, number of
 387 beams and field of view, the proposed approach generated the
 388 sonar frames with a high frame rate, for both sonar types. Given
 389 the Tritech Gemini 720i, a real forward-looking sonar sensor,
 390 with a field of view of 120° by 20° and 256 beams, presents a
 391 maximum update rate of 15 frames per second, the results allow
 392 the use of the sonar simulator for real-time applications. Also,
 393 the MSIS data built by the simulator is able to complete a 360°
 394 scan sufficiently fast in comparison with a real sonar as Tritech

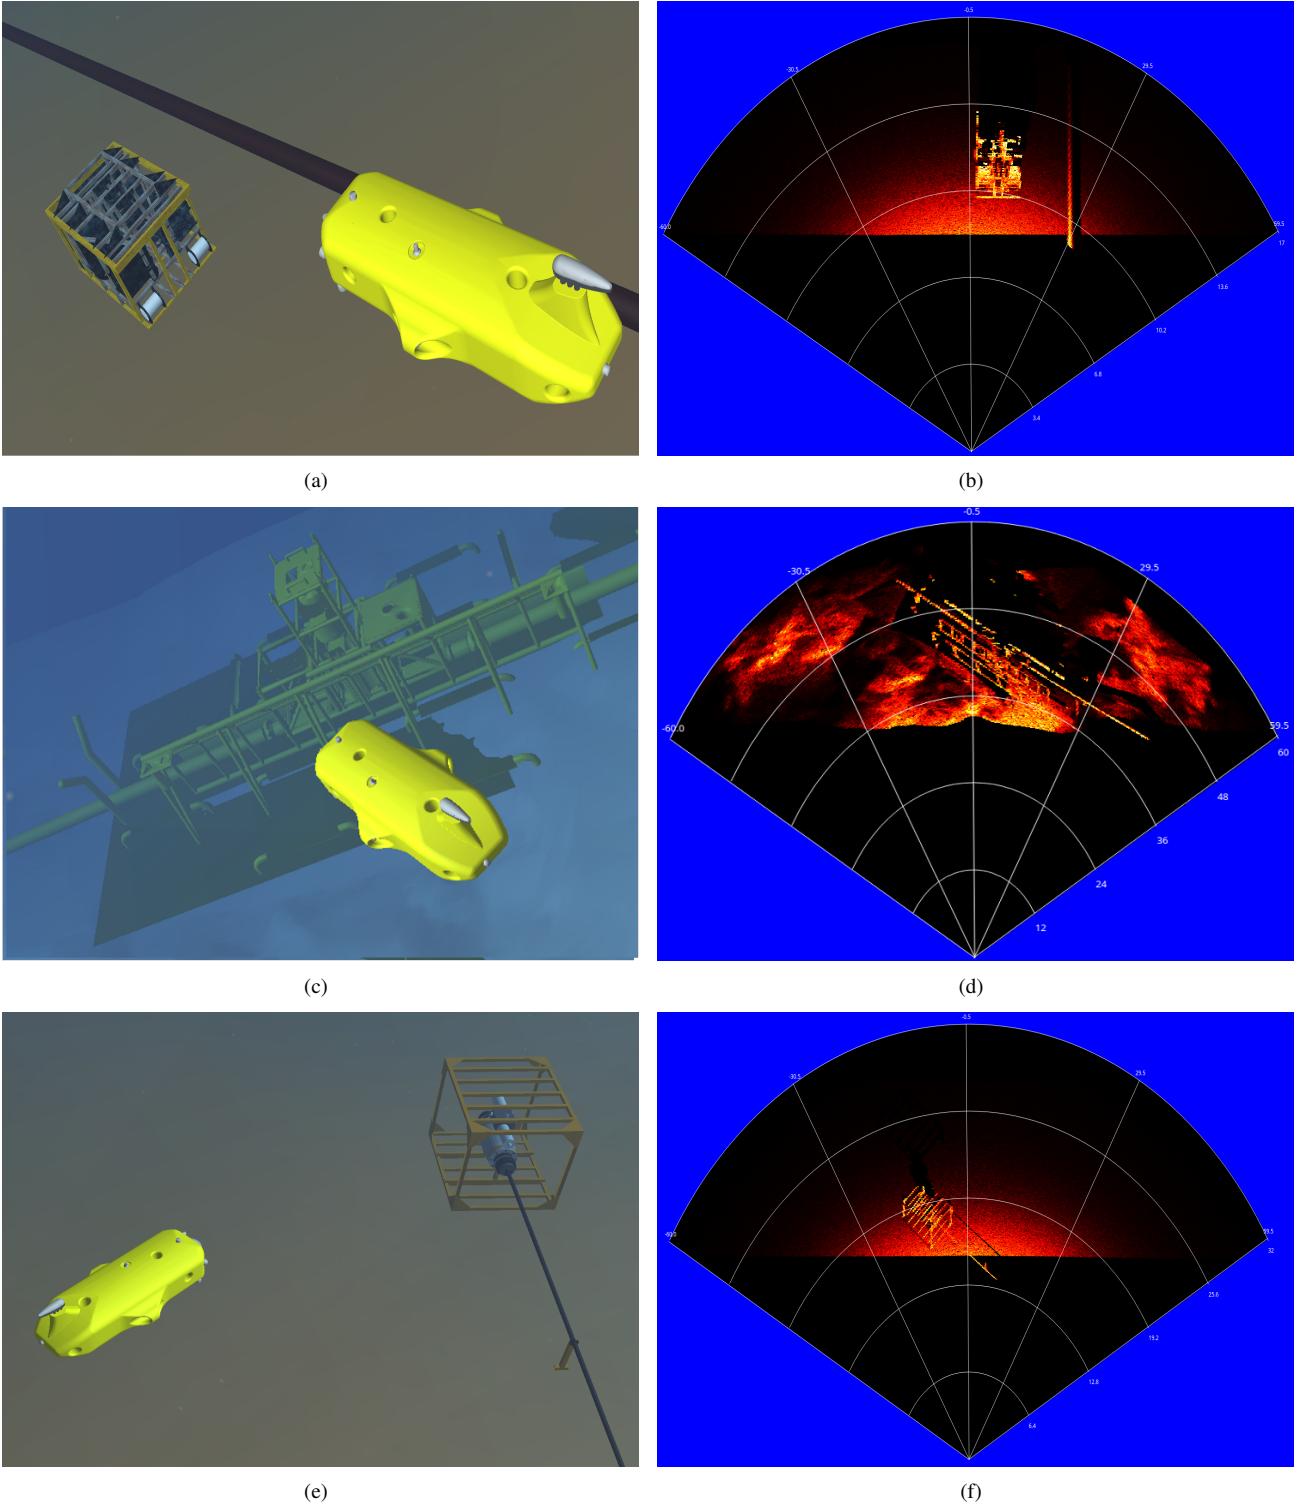

Figure 7: Forward-looking sonar simulation experiments: (a), (c) and (e) present the virtual underwater trials, while (b), (d) and (f) are the following acoustic representations of each scenario, respectively.

395 Micron DST. Moreover, for the FLS device, these rates are su-
 396 perior to the rates lists by DeMarco *et al* [5] (330ms) and Saç
 397 *et al* [4] (2.5min). For MSIS type, to the best of our knowledge,
 398 there is no previous work done for comparison.

399 According to previous results, since the number of bins is

400 directly proportional to sonar image resolution, as explained in
 401 Section 3.3, this is also correlated with the computational time.
 402 When the number of bins increases, the simulator will have a
 403 bigger scene frame to compute, and generate the sonar data.

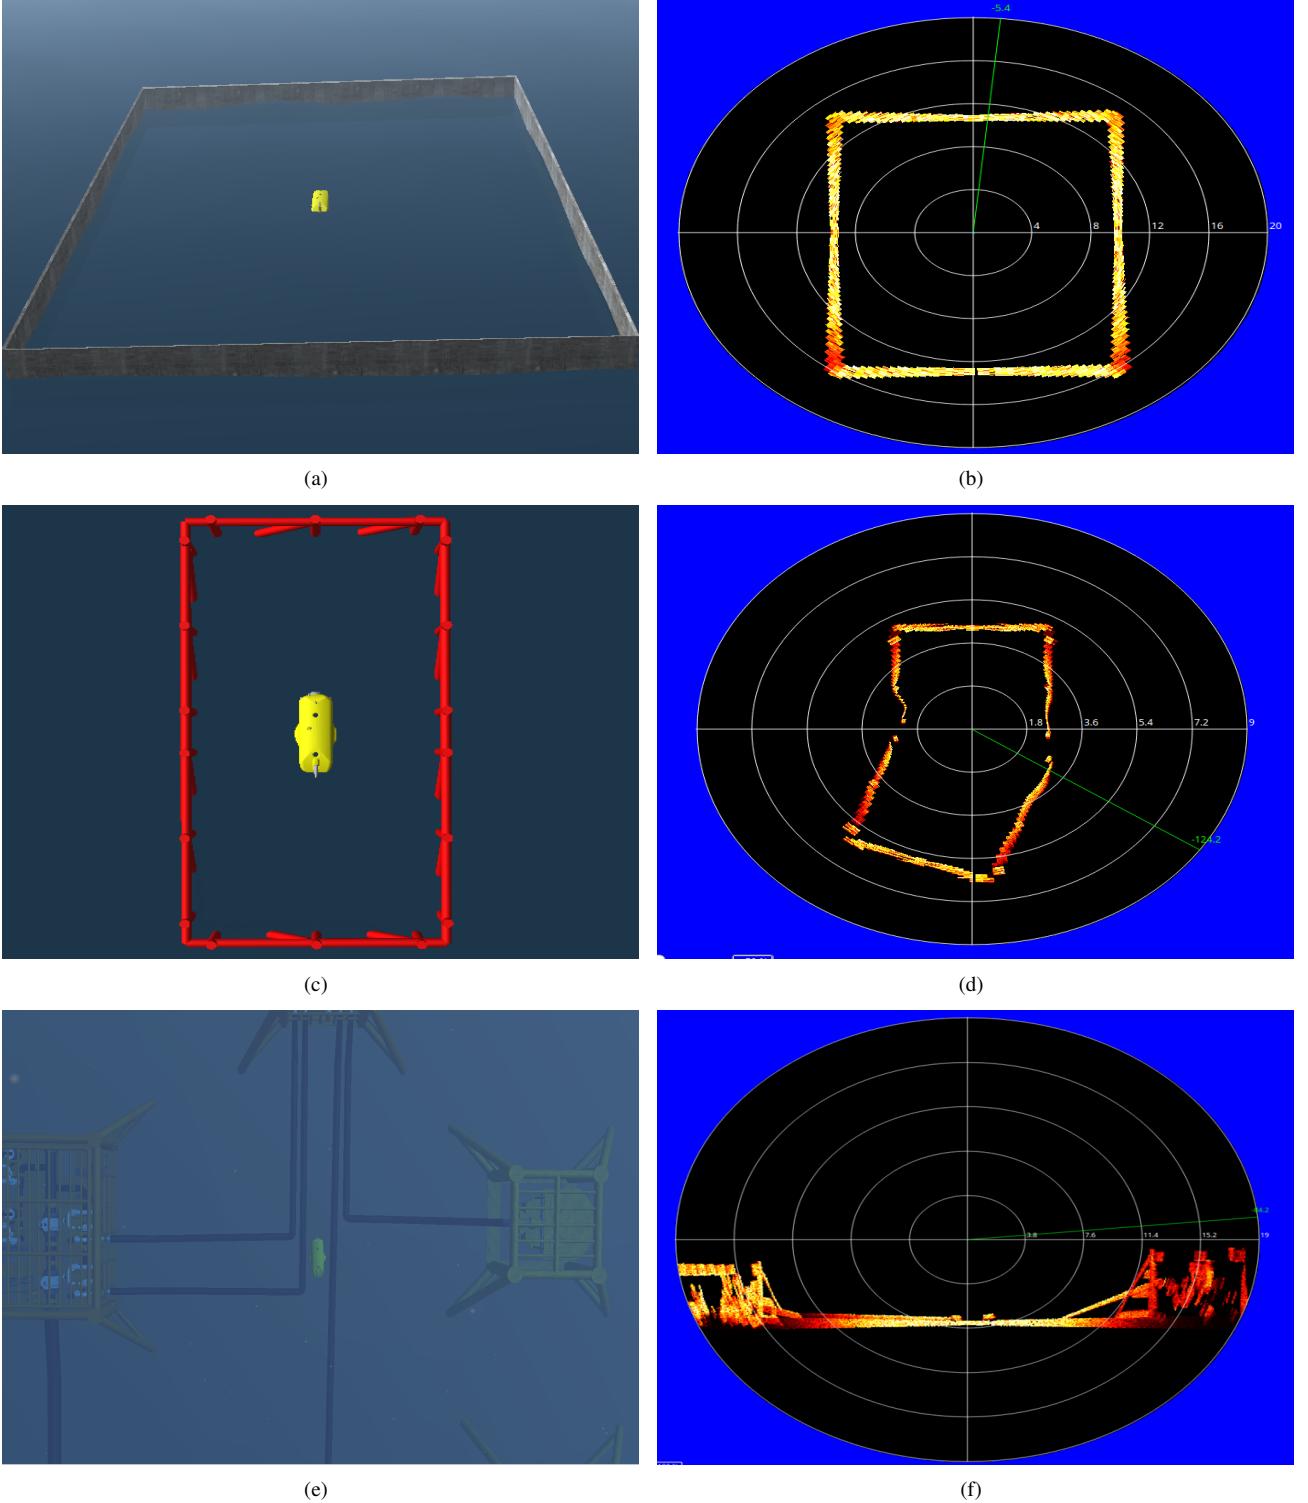

Figure 8: Experiments using mechanical scanning imaging sonar in three different scenarios (a), (c) and (e), and the respective processed simulated frames in horizontal axis in (b) and (d), and vertical axis in (f).

404 5. Conclusion and future work

405 A GPU-based approach for imaging sonar simulation is pre-
 406 sented here. The same model was able to reproduce the oper-
 407 ation mode of two different types of sonar devices (FLS and

408 MSIS) over different scenarios. The real sonar image singulari-
 409 ties, such as multiplicative noise, surface properties and acous-
 410 tic shadows are addressed and represented in the simulated frames.
 411 Specially for the shadows, the acoustic representation can present
 412 information as useful as the insonified object. Considering the

Table 2: Processing time to generate forward-looking sonar frames with different parameters.

# of samples	# of beams	# of bins	Field of view	Average time (ms)	Std dev (ms)	Frame rate (fps)
500	128	500	120° x 20°	54.7	3.7	18.3
500	128	1000	120° x 20°	72.3	8.9	13.8

500	128	500	90° x 15°	77.4	11.8	12.9
500	128	1000	90° x 15°	94.6	10.2	10.6
500	256	500	90° x 15°	260.8	18.5	3.8
500	256	1000	90° x 15°	268.7	16.7	3.7

Table 3: Processing time to generate mechanical scanning imaging sonar samples with different parameters.

# of samples	# of bins	Field of view	Average time (ms)	Std dev (ms)	Frame rate (fps)
500	500	3° x 35°	8.8	0.7	113.4
500	1000	3° x 35°	34.5	1.6	29.0
500	500	2° x 20°	10.3	0.6	96.7
500	1000	2° x 20°	41.7	3.7	24.0

413 qualitative results, the sonar simulator can be used by feature
414 detection algorithms, based on corners, lines and shapes. Also,
415 the computation time to build one sonar frame was calculated
416 using different device settings. The vertex and fragment pro-
417 cessing during the underwater scene rendering accelerates the
418 sonar image building, and the metrics, such as the average time,
419 demonstrated that the performance is much close to real imag-
420 ing devices. These results allowed the use of this imaging sonar
421 simulator by real-time applications, such as obstacle detection
422 and avoidance, and object tracking. Finally, the reverberation
423 effect is still missing on our simulator to perform a more realis-
424 tic sensing. The future inclusion of this phenomenon will prob-
425 ably change the reflected intensity model and the computation
426 time must be considered again. Next steps will focus on expand
427 the underwater acoustic characteristics, such as additive noise
428 and reverberation, and qualitative and computation-efficiency
429 evaluations with other imaging sonar simulators.
